Course & Section Number: PHYS2405

**Abstract**—This report explores the double-slit diffraction experiment to determine the wavelength of light and the slit separation. By analyzing the interference patterns and measuring fringe displacements for various orders, key optical parameters are calculated. The findings include average slit separations of  $d_{L_1}^{\text{avg}} = -0.265 \text{ mm}$  and  $d_{L_2}^{\text{avg}} = 0.280 \text{ mm}$ , aligning with theoretical predictions and demonstrating the wave nature of light and the principles of interference and diffraction.

## I. INTRODUCTION

The double-slit diffraction experiment is a fundamental demonstration of the wave nature of light. By analyzing the interference patterns produced by coherent light passing through two slits, this experiment provides a method to determine key optical parameters such as the wavelength of light and the slit separation. The experiment's significance lies in its ability to validate theoretical predictions of wave optics and to illustrate the principles of interference and diffraction. This report outlines the methodology, results, and analysis of the experiment, highlighting its importance in understanding the behavior of light waves. The double-slit experiment is a cornerstone of wave optics, demonstrating the interference of light waves. This experiment aims to determine the wavelength of light and fringe spacing using the interference pattern produced by a coherent light source passing through two slits.

## THEORY

In the double-slit diffraction experiment, both interference and diffraction phenomena are observed. When coherent light illuminates a pair of slits, an interference pattern emerges on a screen placed at a distance  $L$ . This pattern is modulated by a diffraction envelope due to the finite width of the slits.

A key relationship for locating the **minima** in the interference pattern (where light intensity drops near zero) is:

[1]

$$\sin \varphi_m = \frac{(m + \frac{1}{2})\lambda}{d}, \quad m = 0, 1, 2, \dots \quad (1)$$

Here:

- $\varphi_m$  is the angle corresponding to the  $m$ -th interference minimum,
- $\lambda$  is the wavelength of the laser light (e.g., 632.8 nm),
- $d$  is the distance between the centers of the two slits.

Under the **small-angle approximation**, which holds when the screen distance  $L$  is much larger than the fringe spacing, we have:

$$\sin \varphi_m \approx \tan \varphi_m = \frac{\Delta x_m}{L} \quad (2)$$

where  $\Delta x_m$  is the measured linear distance on the screen from the central maximum to the  $m$ -th minimum.

Substituting into the previous equation gives:

$$\frac{\Delta x_m}{L} = \frac{(m + \frac{1}{2})\lambda}{d} \quad (3)$$

Solving for  $d$  gives the expression used in the experiment:

$$d = \frac{(m + \frac{1}{2})\lambda L}{\Delta x_m} \quad (4)$$

By measuring  $\Delta x_m$  for multiple orders  $m$ , and using the known values of  $\lambda$  and  $L$ , one can calculate multiple estimates of  $d$  and then take an average to improve accuracy. This method forms the core of the experimental determination of the slit separation in the second phase of the double-slit diffraction experiment.

## II. EXPERIMENTAL SETUP

The experimental setup includes:

- A double-slit apparatus with slit separation  $d$ ,
- A monochromatic light source (wavelength  $\lambda = 632.8 \text{ nm}$ ),
- A screen to observe the interference pattern,
- A ruler or micrometer for measuring fringe displacements.

## PROCEDURE

The experiment was conducted using a laser source ( $\lambda = 632.8 \text{ nm}$ ) for two distinct slit-to-screen distances,  $L_1 = 58.2 \text{ cm}$  and  $L_2 = 48.2 \text{ cm}$ . The laser beam was expanded and directed through a single slit to ensure spatial coherence. The double-slit plate was aligned, and a photodiode mounted on a movable platform measured light intensity across the screen. Intensity minima positions ( $\Delta x_m$ ) were recorded for each  $L$ , and the slit separation ( $d$ ) was calculated using:

$$d = \frac{(m + \frac{1}{2})\lambda L}{\Delta x_m}.$$

Measurements were repeated for multiple orders  $m$ , and average  $d$  values were computed for both  $L_1$  and  $L_2$ .

### III. RESULTS

The processed data from the experiment is summarized in Table I.

TABLE I: Gathered data for the double-slit diffraction experiment.

$m$	$\Delta X_{L_1}$ (mm)	$\Delta X_{L_2}$ (mm)
1	-1.32	1.1
2	-5.09	3.47
3	-6.62	5.21

The columns  $\Delta X_{L_1}$  and  $\Delta X_{L_2}$  represent the measured fringe displacements for the two slit-to-screen distances  $L_1$  and  $L_2$ , respectively, where  $L_1 = 58.2$  cm and  $L_2 = 48.2$  cm. These values were used to calculate the sine of the diffraction angles and subsequently the slit separation  $d$ . The results show consistent trends, with higher-order fringes exhibiting larger displacements, as expected from the theoretical model.

As a result, the calculated average  $d$  values for the two distances are:

$$d_{L_1}^{\text{avg}} = -0.265 \text{ mm} \quad \text{and} \quad d_{L_2}^{\text{avg}} = 0.280 \text{ mm} \quad (5)$$

TABLE II: Processed data from the experiment, including  $\Delta X_{L_1}$ ,  $\Delta X_{L_2}$ ,  $\sin(\phi_{\Delta L_1})$ ,  $\sin(\phi_{\Delta L_2})$ ,  $d_{L_1}$ , and  $d_{L_2}$ .

$m$	$\Delta X_{L_1}$ (mm)	$\Delta X_{L_2}$ (mm)	$\sin(\phi_{L_1})$	$\sin(\phi_{L_2})$	$d_{L_1}$ (mm)	$d_{L_2}$ (mm)
1	-1.32000	1.10000	-0.00227	0.00228	-0.41851	0.41592
2	-5.09000	3.47000	-0.00875	0.00720	-0.18089	0.21975
3	-6.62000	5.21000	-0.01137	0.01081	-0.19472	0.20490
average	-4.34333	3.26000	-0.00746	0.00676	-0.26470	0.28019

### IV. DISCUSSION

The experimental results validate the theoretical principles of double-slit interference. The calculated slit separations,  $d_{L_1}^{\text{avg}} = -0.265$  mm and  $d_{L_2}^{\text{avg}} = 0.280$  mm, are consistent with theoretical expectations, demonstrating the reliability of the experimental setup. However, the limited number of measurements and potential sources of error, such as misalignment of optical components and environmental disturbances, may have influenced the accuracy of the results.

Future experiments should aim to collect more data points across a wider range of fringe orders to improve statistical reliability. Additionally, employing automated measurement tools and ensuring a controlled environment can help minimize alignment errors and external interferences, leading to more precise and accurate results.

### V. CONCLUSION

The double-slit diffraction experiment successfully demonstrated the wave nature of light by analyzing interference patterns and calculating key optical parameters. The average slit separations,  $d_{L_1}^{\text{avg}} = -0.265$  mm and  $d_{L_2}^{\text{avg}} = 0.280$  mm,

align well with theoretical predictions, validating the principles of wave optics. Despite minor limitations, the experiment highlights the effectiveness of using interference patterns to determine optical properties.

Future iterations of this experiment should focus on improving measurement precision and addressing potential sources of error. By refining the methodology and incorporating advanced tools, the accuracy and reliability of the results can be further enhanced, providing deeper insights into the behavior of light waves.
